Abstract

The cross sections of the processes ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$ are calculated taking into account the full final state interaction via the Lorentz integral transform (LIT) method. This is the first consistent microscopic calculation beyond the three-body breakup threshold. The results are obtained with a semirealistic central NN potential including also the Coulomb force. The cross sections show a pronounced dipole peak at 27 MeV which lies within the rather broad experimental band. At higher energies, where experimental uncertainties are considerably smaller, one finds a good agreement between theory and experiment. The calculated sum of three- and four-body photodisintegration cross sections is also listed and is in fair agreement with the data.

I. INTRODUCTION

The photodisintegration of the ${}^4\text{He}$ nucleus has a longstanding history. First experiments on the (γ, n) reaction were performed some 50 years ago [1]. In the following 25 years various experimental groups carried out measurements for both the ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$ reaction channels and the inverse capture reactions [2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15]. Dramatically conflicting results have been obtained as a result of this work. The (γ, p) data were consistent in showing a rather pronounced resonant peak close to the three-body breakup threshold. At the same time, the (γ, n) data at low energy were very spread, and measurements showed either a strongly pronounced or a rather suppressed giant dipole peak. In 1983 a careful and balanced review of all the available experimental data for the two mirror reactions was provided [16]. A strongly peaked cross section at low energy for the (γ, p) channel and a flatter shape for the (γ, n) one was recommended by the authors. Three new experiments on the (γ, p) reaction were subsequently carried out, two of them contradicting and one confirming the recommended cross section. In particular in [17] and [18] a suppressed dipole resonance was found, whereas [19] proved to be in agreement with the previous strongly peaked results. Measurements of the ratio of the (γ, p) to (γ, n) cross sections in the giant resonance region were performed as well and, at variance with the cross sections recommended in [16], results very close to unity were reported [21, 22]. Finally, in 1992 additional cross section data were deduced from a Compton scattering experiment on ${}^4\text{He}$ [20]. A strongly peaked cross section for the ${}^4\text{He}$ total photoabsorption was found suggesting a (γ, n) cross section considerably larger than the one recommended in [16].

In 1996 the first theoretical calculation of the two-fragment breakup cross section with inclusion of final state interaction (FSI) was performed in the energy range below the three-fragment breakup threshold [23]. The semi-realistic MTI-III potential [24] was employed. The results of [23] showed a rather suppressed giant dipole peak. The following year a calculation of the total ${}^4\text{He}$ photoabsorption cross section up to the pion threshold was carried out [25]. Full FSI was taken into account in the whole energy range via the Lorentz integral transform (LIT) method [26] that does not require calculating continuum wave functions. The four-nucleon dynamics was described with the same NN potential as in [23]. Different from the previous work a pronounced giant dipole peak was found [25]. These results have been reexamined in [27]. A small shift of the peak position has been obtained,

but the pronounced peak has been confirmed.

In order to understand the origin of the large total photonuclear cross section in terms of the various channel contributions, a separate calculation of the channel cross sections is necessary. The present paper reports a theoretical study of the two-fragment breakup processes ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$. For these exclusive reactions we investigate the issue of the giant dipole peak height, and we also calculate the cross section at higher energies, up to the pion threshold. The calculation includes full FSI via the LIT method [28] and employs the semi-realistic MTI-III potential [24].

The LIT method has already been successfully tested for exclusive reactions in the $d(e, e'p)n$ process [29]. The present calculation represents the first application to $A > 2$. We would like to emphasize that in our study FSI is taken into account rigorously also beyond the three- and four-body breakup thresholds. In addition, combining our cross sections with the total photoabsorption cross section calculated in [25, 27] for the same potential, we obtain the sum of three- and four-body photodisintegration cross sections of ${}^4\text{He}$, for which some experimental data are available [30, 31, 32, 33].

II. GENERAL FORMALISM

A. Cross Section

The total exclusive cross section of the ${}^4\text{He}$ photodisintegration into the two fragments N and β , where N refers to the scattered proton (neutron) and β refers to the ${}^3\text{H}$ (${}^3\text{He}$) nucleus, is given by

$$\sigma_{N,\beta} = \frac{e^2}{\hbar c} \frac{k\mu\omega_\gamma}{4\pi} \int |\langle \Psi_{N,\beta}^-(E_{N,\beta}) | D_z | \Psi_\alpha \rangle|^2 d\Omega_k, \quad E_{N,\beta} = \omega_\gamma + E_\alpha. \quad (1)$$

In the equation above we neglect the very small nuclear recoil energy. With μ and k we denote the reduced mass and the relative momentum of the fragments, respectively, ω_γ is the incident photon energy, Ψ_α is the ground-state wave function, $\Psi_{N,\beta}^-$ is the final-state continuum wave function of the minus type pertaining to the N,β channel [34], and E_α and $E_{N,\beta}$ are the energies of the corresponding initial and final states, respectively. As in [25, 27] only transitions induced by the unretarded dipole operator,

$$D_z = \sum_{j=1}^4 \tau_j^3 z_j \quad (2)$$

are taken into account. Here τ_j^3 denotes the third component of the j -th nucleon isospin and z_j represents the z component of the distance between the j -th nucleon and the center of mass of the system. This form of the transition operator already includes the leading effects of meson exchange currents via Siegert's theorem. Additional contributions to the total cross section are small at the energies considered here (see also [35, 36]).

The main difficulty in the calculation of such a cross section is the presence of the continuum wave function $\Psi_{N,3}^-(E_{N,3})$ in the transition matrix element

$$T_{N,3}(E_{N,3}) = \langle \Psi_{N,3}^-(E_{N,3}) | D_z | \Psi_\alpha \rangle . \quad (3)$$

As it will be explained in the next subsection, with the LIT method one is able to perform an *ab initio* calculation of this transition matrix element in the whole energy range below the pion threshold without dealing with the continuum solutions of the four-body Schrödinger equation.

B. The LIT Method for Exclusive Reactions

For the case of an exclusive perturbation-induced process, all the information about the reaction dynamics is contained in the transition matrix element of the perturbation $\hat{O}$ between the initial (Ψ_0) and final (Ψ_f^-) states,

$$T_f(E_f) = \langle \Psi_f^-(E_f) | \hat{O} | \Psi_0 \rangle . \quad (4)$$

The calculation of such a matrix element can be carried out with the LIT method as outlined in the following [28, 29]. For simplicity we restrict our discussion to an exclusive reaction leading to a final state with two fragments, a fragment a with n_a nucleons and a fragment b with $n_b = A - n_a$ nucleons, though more complex fragmentations of the initial A -body system can be treated as well. Denoting with H the full nuclear Hamiltonian we have a formal expression for $\Psi_{f=a,b}^-$ in terms of the "channel state" $\phi_{f=a,b}^-(E_{f=a,b})$ [34],

$$|\Psi_{a,b}^-(E_{a,b})\rangle = \hat{\mathcal{A}} |\phi_{a,b}^-(E_{a,b})\rangle + \frac{1}{E_{a,b} - i\varepsilon - H} \hat{\mathcal{A}} \mathcal{V} |\phi_{a,b}^-(E_{a,b})\rangle , \quad (5)$$

where $\hat{\mathcal{A}}$ is an antisymmetrization operator. When there is no Coulomb interaction in the system, the channel state $\phi_{a,b}^-(E_{a,b})$ is the product of the internal wave functions of the fragments and of their relative free motion. Correspondingly, $\mathcal{V}$ in Eq. (5) is the sum

of all interactions between particles belonging to different fragments. In the general case, $\phi_{a,b}^-(E_{a,b})$ is chosen to account for the average Coulomb interaction between the fragments, and the plane wave describing their relative motion is replaced by the Coulomb function of the minus type. We write down this function in the partial wave expansion form

$$\phi_{a,b}^-(E_{a,b}) = \frac{\Phi_a(1, \dots, n_a)\Phi_b(n_a + 1, \dots, A)}{(2\pi)^{3/2}} 4\pi \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} i^{\ell} e^{-i\delta_{\ell}(k)} \frac{w_{\ell}(k; r)}{kr} Y_{\ell m}(\Omega_r) Y_{\ell m}^*(\Omega_k). \quad (6)$$

Here $\Phi_a(1, \dots, n_a)$ and $\Phi_b(n_a + 1, \dots, A)$ are the internal wave functions of the the fragments, $\mathbf{r} = (r, \Omega_r) = \mathbf{R}_{cm}^a - \mathbf{R}_{cm}^b$ represents the distance between them, and the energy of the relative motion is $k^2/2\mu = E_{a,b} - E_a - E_b$, where E_a and E_b are the fragment ground state energies. The functions $w_{\ell}(k; r)$ are the regular Coulomb wave functions of order ℓ , and $\delta_{\ell}(k)$ are the Coulomb phase shifts [34].

The internal wave functions of the fragments are assumed to be antisymmetrized and normalized to unity, so that the properly normalized continuum wave function in Eq. (5) is obtained via application of the antisymmetrization operator

$$\hat{\mathcal{A}} = \sqrt{\frac{n_a!n_b!}{A!}} \left[1 - \sum_{i=1}^{n_a} \sum_{j=n_a+i}^A \mathcal{P}_{ij} \right], \quad (7)$$

where $\mathcal{P}_{ij}$ are particle permutation operators [34].

When one inserts Eq. (5) into Eq. (4) the transition matrix element becomes the sum of two pieces, a Born term,

$$T_{a,b}^{Born}(E_{a,b}) = \left\langle \phi_{a,b}^-(E_{a,b}) \left| \hat{\mathcal{A}} \hat{O} \right| \Psi_0 \right\rangle, \quad (8)$$

and an FSI dependent term,

$$T_{a,b}^{FSI}(E_{a,b}) = \left\langle \phi_{a,b}^-(E_{a,b}) \left| \mathcal{V} \hat{\mathcal{A}} \frac{1}{E_{a,b} + i\varepsilon - H} \hat{O} \right| \Psi_0 \right\rangle. \quad (9)$$

While the Born term is rather simple to deal with, the determination of the FSI dependent matrix element is rather complicated. We treat this term within the LIT approach as outlined in the following.

Let $\Psi_{\nu}(E_{\nu})$ be the eigenstates of the Hamiltonian labelled by channel quantum numbers ν and normalized as $\langle \Psi_{\nu} | \Psi_{\nu'} \rangle = \delta(\nu - \nu')$. Using the completeness relation of the set $\Psi_{\nu}(E_{\nu})$ the matrix element $T_{a,b}^{FSI}(E_{a,b})$ can be written as:

$$\begin{aligned} T_{a,b}^{FSI}(E_{a,b}) &= \sum_{\nu} d\nu \langle \phi_{a,b}^-(E_{a,b}) | \mathcal{V} \hat{\mathcal{A}} | \Psi_{\nu}(E_{\nu}) \rangle \frac{1}{E_{a,b} + i\varepsilon - E_{\nu}} \langle \Psi_{\nu}(E_{\nu}) | \hat{O} | \Psi_0 \rangle \\ &= \int_{E_{th}}^{\infty} \frac{F_{a,b}(E)}{E_{a,b} + i\varepsilon - E} dE = -i\pi F_{a,b}(E_{a,b}) + \mathcal{P} \int_{E_{th}}^{\infty} \frac{F_{a,b}(E)}{E_{a,b} - E} dE, \end{aligned} \quad (10)$$

where $F_{a,b}(E)$ is defined as

$$F_{a,b}(E) = \sum \int d\nu \left\langle \phi_{a,b}^-(E_{a,b}) \left| \mathcal{V} \hat{\mathcal{A}} \right| \Psi_\nu(E_\nu) \right\rangle \left\langle \Psi_\nu(E_\nu) \left| \hat{O} \right| \Psi_0 \right\rangle \delta(E - E_\nu) , \quad (11)$$

and E_{th} is the lowest excitation energy in the system i.e. the breakup threshold energy. To calculate $T_{a,b}$ one needs to know the function $F_{a,b}$ for all energy values. The direct calculation of $F_{a,b}$ is of course far too difficult, since one should know all the eigenstates Ψ_ν for the whole eigenvalue spectrum of H . However, an indirect calculation of $F_{a,b}$ is possible applying the LIT method. To this end, one introduces an integral transform of $F_{a,b}$ with a kernel of Lorentzian shape,

$$\begin{aligned} L[F_{a,b}](\sigma) &= \int_{E_{th}^-}^{\infty} \frac{F_{a,b}(E)}{(E - \sigma_R)^2 + \sigma_I^2} dE = \int_{E_{th}^-}^{\infty} \frac{F_{a,b}(E)}{(E - \sigma)(E - \sigma^*)} dE \\ &= \sum \int d\nu \left\langle \phi_{a,b}^-(E_{a,b}) \left| \mathcal{V} \hat{\mathcal{A}} \frac{1}{H - \sigma^*} \right| \Psi_\nu(E_\nu) \right\rangle \left\langle \Psi_\nu(E_\nu) \left| \frac{1}{H - \sigma} \hat{O} \right| \Psi_0 \right\rangle \\ &= \left\langle \tilde{\Psi}_2(\sigma) \left| \tilde{\Psi}_1(\sigma) \right\rangle , \end{aligned} \quad (12)$$

with $\sigma = \sigma_R + i\sigma_I$. Here we denote

$$\tilde{\Psi}_1(\sigma) = (H - \sigma)^{-1} \hat{O} |\Psi_0\rangle , \quad \tilde{\Psi}_2(\sigma) = (H - \sigma)^{-1} \hat{\mathcal{A}} \mathcal{V} |\phi_{a,b}^-(E_{a,b})\rangle . \quad (13)$$

Equation (12) shows that $L[F_{a,b}](\sigma)$ can be calculated without explicit knowledge of $F_{a,b}$ provided that one solves the two equations,

$$(H - \sigma) \left| \tilde{\Psi}_1 \right\rangle = \hat{O} |\Psi_0\rangle , \quad (14)$$

$$(H - \sigma) \left| \tilde{\Psi}_2 \right\rangle = \hat{\mathcal{A}} \mathcal{V} |\phi_{a,b}^-(E_{a,b})\rangle \quad (15)$$

which differ in the source terms only.

It can be seen that $\tilde{\Psi}_1$ and $\tilde{\Psi}_2$ are localized i.e. have finite norms. Assuming that $\sigma_I \neq 0$ this is ensured by the fact that the source terms in the right-hand sides of Eqs. (14) and (15) are localized. In fact in the coordinate representation the source term in Eq. (14) decreases exponentially for increasing distances between particles. The source term in Eq. (15) contains two potential contributions i.e. the nuclear force component and the Coulomb interaction. The contribution due to the nuclear interaction vanishes exponentially for increasing distances between particles. Since the average Coulomb potential between the fragments is already taken into account via Eq. (6), the remaining Coulomb contribution behaves like r^{-2} , as the distance r from the fragments increases. Therefore the source term

remains localized also in the presence of the Coulomb force. In our calculation this Coulomb term arises in case of the $p, {}^3\text{H}$ channel and its contribution to the results is found to be very small.

In case of breakups into more than two fragments it is convenient to write Eq. (12) in another form:

$$\begin{aligned} L[F_{a,b}](\sigma) &= \frac{1}{2i\sigma_I} \left\langle \phi^-(E_{a,b}) \left| \mathcal{V}\hat{\mathcal{A}} \left[\frac{1}{H-\sigma} - \frac{1}{H-\sigma^*} \right] \hat{\mathcal{O}} \right| \Psi_0 \right\rangle \\ &= \frac{1}{2i\sigma_I} \left[\left\langle \phi_{a,b}^-(E_{a,b}) \left| \mathcal{V}\hat{\mathcal{A}} \right| \tilde{\Psi}_1(\sigma) \right\rangle - \left\langle \phi_{a,b}^-(E_{a,b}) \left| \mathcal{V}\hat{\mathcal{A}} \right| \tilde{\Psi}'_1(\sigma) \right\rangle \right]. \end{aligned} \quad (16)$$

Here $\tilde{\Psi}_1(\sigma)$ is the same as above, and $\tilde{\Psi}'_1(\sigma)$ satisfies

$$(H - \sigma^*) \left| \tilde{\Psi}'_1(\sigma) \right\rangle = \hat{\mathcal{O}} \left| \Psi_0 \right\rangle. \quad (17)$$

Therefore, also in this case, one has to deal with a localized solution.

When solving Eqs. (14), (15) and (17) it is sufficient to require that the solutions are localized, and no other boundary conditions are to be imposed. Therefore, similar to what is done in bound state calculations, one can use an expansion over a basis set of localized functions. A convenient choice is the basis set consisting of correlated hyperspherical harmonics (CHH) multiplied by hyperradial functions.

As discussed in [27] for the case of the total ${}^4\text{He}$ photoabsorption cross section, special attention has to be paid to the convergence of such expansions. A rather large number of basis states is necessary in order to reach convergence, thus leading to large Hamiltonian matrices. Instead of using a time consuming inversion method we directly evaluate the scalar products in (16) with the Lanczos technique [37]. Inserting the Lanczos orthonormal basis $\{\varphi_i, i = 0, \dots, n\}$ into Eq. (16), where φ_o is taken to be the right-hand side (normalized to unity) of Eqs. (14), (17), one gets

$$L[F_{a,b}](\sigma) = \frac{\sqrt{\langle \Psi_0 | \hat{\mathcal{O}}^\dagger \hat{\mathcal{O}} | \Psi_0 \rangle}}{2i\sigma_I} \sum_{i=0}^n \left\langle \phi_{a,b}^-(E_{a,b}) \left| \mathcal{V}\hat{\mathcal{A}} \right| \varphi_i \right\rangle \left\langle \varphi_i \left| \frac{1}{H-\sigma} - \frac{1}{H-\sigma^*} \right| \varphi_o \right\rangle. \quad (18)$$

The matrix elements $\langle \varphi_i | (H - \sigma)^{-1} | \varphi_o \rangle$ can be written as continued fractions of the Lanczos coefficients.

After having calculated $L[F_{a,b}](\sigma)$ one obtains the function $F_{a,b}(E)$, and thus $T_{a,b}(E_{a,b})$, via the inversion of the LIT, as described in [38].

III. RESULTS

The ground states of ^4He , ^3He and ^3H as well as the LIT in Eq. (18) are calculated using the CHH expansion method. In order to speed up the convergence, state independent correlations are introduced as in [39]. We use the MTI-III [24] potential and identical CHH expansions for the ground state wave functions of ^4He and of the three-nucleon systems as in [27] and [40], respectively.

Because of the choice of the excitation operator (see Eq. (2)), in solving Eqs. (14) and (15) the HH must be characterized by the quantum numbers $L=1$, $S=0$ and $T=1$. In this calculation the maximal value of the grand-angular quantum number, K_{max} , is equal to 29. Such a high value of K_{max} has been made possible by neglecting states which have proved to give very small contributions to the LIT. The choice of these states has been done in the following way. Our hyperspherical harmonics (HH) depend on three Jacobi vectors ξ_1, ξ_2, ξ_3 , among which ξ_1 represents the distance between a pair of particles. The HH entering the calculation are obtained via symmetrization of the HH possessing a definite relative orbital momentum ℓ_1 associated with ξ_1 and a definite grand-angular momentum $\tilde{K}$ in the subspace of vectors ξ_2, ξ_3 . We have found that beyond $K_{max} = 13$ we can neglect all symmetrized HH which originate from the non-symmetrized HH with ℓ_1 greater than 2 and $\tilde{K}$ greater than 3 and, beyond $K_{max} = 19$, those with ℓ_1 greater than 0 and $\tilde{K}$ greater than 1. This selection is similar to that justified and used in non-correlated HH bound state calculations (see [41] and references therein). An additional selection has been performed with respect to the permutational symmetry types of the HH. For $S = 0$, $T = 1$ quantum numbers, HH of two permutational symmetry types enter the expansion, those belonging to the irreducible representations $[f] = [+]$ and $[f] = [-]$ of the four-particle permutation group $\mathbf{S}_4$ [39, 41]. For basis states constructed from the HH of the $[+]$ type the probability for a nucleon pair to be in a relative even state and in particular in the s -state is substantially higher. We have found that the contribution to the LIT of states with the spatial symmetry $[-]$ is suppressed, and the corresponding HH with K values higher than 9 can be neglected in the calculation.

In Fig. 1, the convergence of the LIT with respect to K_{max} is shown. One sees that for $K_{max} = 29$ a good convergence is reached.

In Fig. 2 we present our results for the $^4\text{He}(\gamma, n)^3\text{He}$ cross section together with experimental data. The difference between the total cross section and its Born approximation

shows large effects of FSI. At small energies FSI enhances the transition matrix element since the values of the final state continuum wave function inside the reaction zone become larger due to the attraction between the fragments. At higher energies the transition matrix element including FSI becomes smaller than the Born one. This is due to shorter wavelengths (higher particle momenta) leading to faster oscillations in the integrands.

As it was pointed out in the introduction the experimental results do not show a unique picture. In the energy region beyond 35 MeV there is an overall agreement of the data of [4, 6, 8, 9, 11, 12, 42], whereas in the dipole resonance region big discrepancies are present. The data from [4, 8, 9, 10] show a rather pronounced dipole peak, while the more recent ones from [12, 13] show a flatter behavior (for more detailed information see also reviews of (γ, n) experiments [12, 16]). In the low-energy region our full calculation favours the strongly peaked data of [4, 8, 9, 10]. It is seen from the figure that the higher energy experimental cross section agrees quite well with our full calculation. We would like to point out the large effect of FSI in the high-energy tail. This is probably the region where large dependences of the cross sections from the details of the force and in particular of the three-body force are expected (see [43]) and where it would be desirable to have more accurate data.

The present ${}^4\text{He}(\gamma, n){}^3\text{He}$ results are at variance with the previous calculation carried out up to the three-body breakup threshold (AGS calculation with a rank 1 separable potential representation of the MTI-III potential [23]).

The ${}^4\text{He}(\gamma, p){}^3\text{H}$ cross section is compared with data in Fig. 3. The experimental situation is similar to the (γ, n) case considered above. Again some experimental results show a pronounced giant dipole peak at low energies, as in case of [4, 5, 6, 9, 11, 14, 15], and others present much less strength, like [17] and [18]. At higher energies there is quite a satisfactory agreement among experimental data of different groups. As in the ${}^4\text{He}(\gamma, n){}^3\text{He}$ case, our full results have a large cross section in the dipole resonance region and favour the strongly peaked data, while beyond the peak one finds a rather good agreement between our calculation and all data.

In Fig. 4 we show the effect of the Coulomb interaction in the ${}^4\text{He}(\gamma, N){}^3$ reactions. Though the effect is generally rather small, one notices a suppression of the cross section near threshold due to the Coulomb interaction in the (γ, p) case, compensated by an increase at higher energies.

Since the ${}^4\text{He}(\gamma, d)d$ reaction is not induced by the dipole operator of (2), the sum of

the ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$ cross sections has to be equal to the ${}^4\text{He}$ total inclusive photoabsorption cross section below the $n + p + d$ breakup threshold. Comparison of the sum of our exclusive cross sections in this region with the total inclusive photoabsorption cross section calculated independently can therefore serve as a test of our results. To this aim, we have calculated also the total photoabsorption cross section. This was done using the fact that the norm $\langle \tilde{\Psi}_1(\sigma) | \tilde{\Psi}_1(\sigma) \rangle$ represents the LIT of this total cross section. Our present CHH calculation reproduces the results obtained for the total photoabsorption cross section with the effective interaction HH method [27]. This can be considered as one more test of our calculation, and this is accomplished thanks to the present efforts made in order to increase the K_{max} value up to 29.

The comparison of the sum of our cross sections for the ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$ reactions with the CHH total photoabsorption cross section below the three-body breakup threshold is presented in Fig. 5. The agreement of the two curves in this region is quite satisfactory. There is only some discrepancy very close to threshold. The discrepancy could presumably be resolved by a calculation of the LIT in the threshold region with a smaller σ_I . However, this also requires an increase of the number of hyperradial basis functions along with a more precise determination of the nine-dimensional integrals (at present Monte Carlo integrations), and thus a considerable improvement of the numerical calculation. This uncertainty is in any case smaller than the error bars of available experiments in that energy range.

Figure 5 also shows an indirect determination of the 3,4-body breakup cross section, which is obtained by subtraction of the ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$ cross sections from the total photoabsorption cross section in the region where significant differences are found. This more-body breakup cross section is shown in Fig. 6 together with the three- and four-body disintegration data. Though there are some differences at lower energies and the peak of the theoretical cross section is more pronounced, one finds an overall fair agreement between theory and experiment.

In conclusion we summarize our work. We have calculated the total photodisintegration cross section of ${}^4\text{He}$ in the two mirror channels $p, {}^3\text{H}$ and $n, {}^3\text{He}$ with the MTI-III potential using the LIT method and the CHH expansion. For the first time a microscopic calculation for these reactions has been carried out taking fully into account final state interaction also beyond the three- and four-body breakup thresholds. The pronounced dipole resonance

found in the total photonuclear cross sections [25, 27] is almost exhausted by the two-body break up channel. The ${}^4\text{He}(\gamma, p){}^3\text{H}$ and ${}^4\text{He}(\gamma, n){}^3\text{He}$ cross sections we obtain have a very similar structure. Both show a pronounced giant dipole resonance peak at low energy as obtained in a previous calculation of the total ${}^4\text{He}$ photoabsorption cross section with the same NN potential model. This low-energy behavior of the cross section is in agreement with the experimental data of [4, 5, 8, 9, 10, 14, 15, 19] whereas other measurements [12, 13, 17, 18] show less strength. At higher energies there are much less differences among the experimental data and one finds a rather good agreement with the theoretical results. Our indirect determination of the sum of three- and four-body breakup cross sections shows an overall fair agreement with the sum of three- and four-body break-up data.

We hope to have convinced the reader that further theoretical and experimental efforts are necessary for a better understanding of the ${}^4\text{He}$ photodisintegration. The present theoretical results are fully consistent and complete regarding the treatment of the dynamics in the initial and final state, though obtained with a simple NN potential. In order to confirm the size of the giant dipole peak one would need a more realistic description of this process considering modern realistic NN potentials together with a three-nucleon force.

FIG. 1: The Lorentz transform of Eq.(18) for $\sigma_I = 20$ MeV at $E_{n,^3\text{He}} = 27.9$ MeV with various K_{max} values. In the inset the deviations $R = 100 [L(K_{max} = 29) - L(K_{max})]/L(K_{max} = 29)$ are shown.

Acknowledgments

We would like to thank M.A. Marchisio for supplying us with the computer code for the Lanczos algorithm. S.Q. acknowledges **ECT*** for support. The work of N.B. was supported by the Israel Science Foundation (grant no. 202/02). V.D.E. thanks the Department of Physics of the University of Trento for support and hospitality.
